

Data Models, Coordinates, and Geometries

HES 505 Fall 2025: Session 7

Matt Williamson

Today's Plan

1. Ways to view the world
2. What makes data (geo)spatial?
3. Geometries, support, and spatial messiness

How do you view the world?

...As a Series of Objects?

- The world is a series of *entities* located in space.
- Usually distinguishable, discrete, and bounded
- Some spaces can hold multiple entities, others are empty
- Objects are digital representations of entities

...As a Continuous Field

Operationalizing views of space

What is a data model?

- **Data:** a collection of discrete values that describe phenomena
- Your brain stores millions of pieces of data
- Computers are not your brain
 - Need to organize data systematically
 - Be able to display and access efficiently
 - Need to be able to store and access repeatedly
- Data models solve this problem

2 Types of Spatial Data Models

- **Raster:** grid-cell tessellation of an area. Each raster describes the value of a single phenomenon. More next week...
- **Vector:** (many) attributes associated with locations defined by coordinates

The Vector Data Model

- **Vertices** (i.e., discrete x-y locations) define the shape of the vector
- The organization of those vertices define the *shape* of the vector
- General types: points, lines, polygons

(NEON)

Vectors in Action

- Useful for locations with discrete, well-defined boundaries
- Very precise (not necessarily accurate)

The Raster Data Model

- Raster data represent spatially continuous phenomena (NA is possible)
- Depict the alignment of data on a regular lattice (often a square)
- Geometry is implicit; the spatial extent and number of rows and columns define the cell size

Types of Raster Data

- **Regular**: constant cell size; axes aligned with Easting and Northing
- **Rotated**: constant cell size; axes not aligned with Easting and Northing
- **Sheared**: constant cell size; axes not parallel
- **Rectilinear**: cell size varies along a dimension
- **Curvilinear**: cell size and orientation dependent on the other dimension

Types of Raster Data

- **Continuous:** numeric data representing a measurement (e.g., elevation, precipitation)
- **Categorical:** integer data representing factors (e.g., land use, land cover)

What makes data (geo)spatial?

Location vs. Place

- **Place:** an area having unique **physical** and **human** characteristics **interconnected** with other places
- **Location:** the actual position on the earth's surface
- **Sense of Place:** the emotions someone attaches to an area based on experiences
- Place is *location plus meaning*
- **nominal:** (potentially contested) place names
- **absolute:** the physical location on the earth's surface

Describing Absolute Locations

- **Coordinates:** 2 or more measurements that specify location relative to a *reference system*
- Cartesian coordinate system
- *origin* (O) = the point at which both measurement systems intersect
- Adaptable to multiple dimensions (e.g. z for altitude)

Cartesian Coordinate System

Describing location: extent

- How much of the world does the data cover?
- For rasters, these are the corners of the lattice
- For vectors, we call this the bounding box

Describing location: resolution

Resolution is the size of the smallest object that can be distinguished from its background

Resolution is the distance between two points that can be distinguished from each other

Resolution is the distance between two points that can be distinguished from each other

Resolution is the distance between two points that can be distinguished from each other

Resolution is the distance between two points that can be distinguished from each other

Resolution is the distance between two points that can be distinguished from each other

- **Resolution:** the accuracy that the location and shape of a map's features can be depicted
- **Minimum Mapping Unit:** The minimum size and dimensions that can be reliably represented at a given *map scale*.
- Map scale vs. scale of analysis

Geometries and Support

Geometries

- Vectors aggregate the locations of a feature into a geometry
- Most vector operations require simple, valid geometries

POINTS: Individual x, y locations.

ex: Center point of plot locations, tower locations, sampling locations.

LINES: Composed of many (at least 2) vertices, or points, that are connected.

ex: Roads and streams.

POLYGONS: 3 or more vertices that are connected and **closed**.

ex: Building boundaries and lakes.

Valid Geometries

- A **linestring** is *simple* if it does not intersect
- Valid polygons
- Are closed (i.e., the last vertex equals the first)
- Have holes (inner rings) that inside the the exterior boundary
- Have holes that touch the exterior at no more than one vertex (they don't extend across a line) - For multipolygons, adjacent polygons touch only at points
- Do not repeat their own path

Empty Geometries

- Empty geometries arise when an operation produces **NULL** outcomes (like looking for the intersection between two non-intersecting polygons)
- **sf** allows empty geometries to make sure that information about the data type is retained
- Similar to a **data.frame** with no rows or a **list** with **NULL** values
- Most vector operations require simple, valid geometries

Support

Support is the area to which an attribute applies.

For vectors, the attribute-geometry-relationship can be:

- **constant** = applies to every point in the geometry (lines and polygons are just lots of points)
- **identity** = a value unique to a geometry
- **aggregate** = a single value that integrates data across the geometry

Support

Support is the area to which an attribute applies.

For rasters:

- **point** = attribute refers to the cell center
- **cell** = attribute refers to an area similar to the pixel

Take Homes

- Data models translate views of space *into* analytic tools
- Spatial data requires **location**
- We store location in geometries
- We assign attributes to location based on support
